NACA WARTIME REPORTS are reprints of papers originally issued to provide rapid distribution of advance research results to an authorized group requiring them for the war effort. They were previously held under a security status but are now unclassified. Some of these reports were not technically edited. All have been reproduced without change in order to expedite general distribution.

I - COMPARISON OF SPOT-WELD AND RIVET PATTERNS

II 24S-T ALCLAD SHEET - COMPARISON OF

24S-T ALCLAD AND 75S-T ALCLAD

By H. W. Bussell, L. R. Jackson,  
H. J. Grover, and W. W. Boaver

SUMMARY

This report contains detailed results of a number of fatigue tests on spot-welded joints in aluminum alloys. The tests described include:

1. Fatigue tests on spot-welded lap joints in sheets of unequal thickness of alclad 24S-T. These tests indicate that the fatigue strength of a spot-welded joint in sheets of two different gauges is slightly higher than that of a similar joint in two sheets of the thinner gauge but definitely lower than that of a similar joint in two sheets of the thicker gauge.
2. Fatigue tests on spot-welded alclad 75S-T. Spot-welded lap-joint specimens of alclad 75S-T were not any stronger in fatigue than similar specimens of alclad 24S-T.
3. Fatigue tests on lap-joint specimens spot-welded after various surface preparations. These included AC welding wire-brushed surfaces, DC welding wire-brushed surfaces, and DC welding chemically cleaned surfaces. While the AC welds were strongest statically, the DC welds on wire-brushed surfaces were strongest in fatigue. Specimens prepared in this way were very nearly as strong as the best riveted specimens tested for comparison.
4. Fatigue tests on specimens spot-welded with varying voltage so as to include a wide range of static spot-weld strengths. The fatigue strengths were in the same order as the static strengths but showed less range.

5. Fatigue tests on lap-joint specimens with several patterns of spot welds. In general, those patterns which gave highest static strengths gave also highest fatigue strengths.

6. Fatigue tests on lap-joint specimens with various rivet patterns. Again fatigue strengths were in the same order as static strengths. These riveted joints were generally stronger in fatigue than corresponding spot-welded joints.

#### INTRODUCTION

This report describes the results of several investigations which are extensions of previous work. (See references 1, 2, and 3.)

Proceeding reports have given results of tests on lap-joint specimens consisting of two sheets of 24S-T alclad of equal thickness joined by a single row of spot welds in a line transverse to the direction of loading.

Part I of this report describes tests on specimens comprising two sheets of different thickness joined by a single row of spot welds. All other tests described here concern specimens made of two sheets of equal thickness.

Part II describes tests on spot-welded specimens of alclad 75S-T alloy.

Part III gives results of tests on specimens spot-welded after different surface preparations. Part IV describes tests on specimens spot-welded at different voltages to obtain spots of widely varying size and static strength. These tests were made in an endeavor to learn what type of spot weld may be best in fatigue.

Part V describes a series of tests with multi-row lap joints. Part VI describes a few tests with one-row and with two-row riveted joints for comparison against results on spot-welded joints. These two groups of tests allowed some examination of the question of what spot-weld pattern is best in fatigue and of what fatigue joint efficiency may be attainable in spot-welded lap joints.

This investigation, conducted at Battelle Memorial Institute, was sponsored by, and conducted with financial assistance from, the National Advisory Committee for Aeronautics.

Acknowledgment is due Mr. E. S. Jenkins of the Curtiss-Wright Corporation and Dr. Maurice Nolles of the Lockheed Aircraft Corporation for advice and assistance in obtaining materials and jointed specimens for this investigation. Specimens for determining the effects of surface preparation were received through the courtesy of Mr. C. W. Steward of the Curtiss-Wright Corporation. Specimens for determining the effect of range in spot-weld size were furnished through the courtesy of Mr. R. O. McMaster of California Institute of Technology. Specimens of 75S-T were received through the courtesy of Mr. T. Piper of Northrop Aircraft, Inc.

## I. SPOT-WELDED LAP JOINTS IN SHEETS OF UNEQUAL THICKNESS

### Test Pictures and Static Tests

Two lots of specimens have been tested. Lot A comprised specimens using sheet gages 0.032 to 0.040 inch and 0.040 to 0.051 inch. The other lot, B, included gages 0.025 to 0.032 inch, 0.032 to 0.040 inch, and 0.032 to 0.051 inch. Each specimen was made by joining two pieces (each 9 in. long by 5 in. wide) by a single row of spots spaced  $\frac{3}{4}$  inch apart in a line along the center of a 1-inch overlap section. (See, for example, fig. 1D in reference 1.)

Table 1 indicates the welding conditions. Figures 1 and 2 show sectioned welds. Table 2 gives average weld dimensions and static strength values. Values for some specimens made under comparable conditions with equal gage sheets have been included for comparison.

It may be observed from figures 1 and 2 and from table 2 that welds in sheets of unequal gage show generally greater percentage penetration in the thinner sheet. It also may be noted that the static strength of a weld joining different gage sheets is between the strength value for a weld joining two sheets of the thinner gage and the strength value for a weld joining two sheets of the thicker gage. The weld strength for the unequal sheets is nearer the lower of those strengths (that for a weld joining sheets of the lesser gage).

### Fatigue Test Results

Tables 3 and 4 show the fatigue test results for the first lot of specimens. Figure 3 shows load-life curves plotted from

those data for the load ratios 0.25 and 0.75 (curves for  $R = 0.50$  have been omitted to avoid confusion, but these curves do not present any new features).

Table 5 shows fatigue test results for the other lot of samples and figure 4 the load-life curves plotted from these data.

In figures 3 and 4, there have been included curves for specimens made by spot-welding equal gage sheets. Fatigue failures (see, for example, fig. 2d) were similar to those in joints of equal-thickness sheet. In a few cases, at high loads, a button was torn out of the thinner sheet. (See, for example, fig. 2e.) In general, the fatigue-strength values bear out the observation made for static-strength values: the strength of a weld joining different gage sheets is slightly higher than that for a weld joining sheets of the thinner gage and definitely lower than that for a weld joining sheets of the thicker gage. It seems probable that this statement has limitations, and the conclusion should not be extended to unreasonable differences in sheet gage or applied without due regard for the welding conditions concerned.

## II. FATIGUE TESTS ON SPOT-WELDED ALCLAD 75S-T

### Test Pieces and Results of Fatigue Tests

Comparative tests were made on (1) sheet specimens of 75S-T and of 24S-T and on (2) spot-welded lap-joint specimens of 75S-T and of 24S-T. All specimens were made of 0.040-inch alclad sheet.

Monobloc sheet specimens were 1 inch wide at the center section. (See reference 3, fig. 1.) Tables 6 and 7 show data for these specimens, and figure 5 shows resulting load-life curves. The 75S-T does not appear stronger in fatigue than the 24S-T despite the difference in static properties.

Each spot-welded specimen was made of two pieces 9 inches long by 5 inches wide joined by a single row of spots in the center of a 1-inch overlap section. Tables 8 and 9 show the fatigue test results, and figure 6 shows the load-life curves. For lifetimes beyond  $10^5$  cycles and for both load ratios ( $R = 0.25$  and  $R = 0.60$ ) used, the 75S-T specimens appear slightly weaker than the 24S-T specimens. It may be noted that the 75S-T spot welds were slightly (about 8 percent) stronger in static shear than the 24S-T welds.

### Examination of Spot Welds

Figure 7-(a, b) shows spot welds in the alclad 24S-T; while figure 7 (c, d) shows welds in the 75S-T alclad.

Welds in the two materials are similar in size, shape, and general appearance. Hardness readings at the dendritic zone (where fatigue failure generally took place) gave 90 Vickers for the 75S-T against 100 for the 24S-T.

The photographs in figure 7 show characteristic fatigue failures. Except for the weld in figure 7b, the welds were from specimens loaded similarly (116 lb per spot at  $R = 0.25$ ). It may be noted that failure in the 75S-T welds (c, d) occurred at the projection of the inner alclad. Failure in the 24S-T (a) took place in the sheet outside the weld slug. However, at higher loads (b), failure in the 24S-T occurred at the projection of the inner alclad.

### Conclusions

For the tests made, spot-welded 75S-T seemed no stronger in fatigue than spot-welded 24S-T.

It should be remembered that several factors may be concerned: the relative strengths of bare sheet materials, the effect of the cladding, and the type of spot weld.

## III. LAP-JOINT SPECIMENS SPOT-WELDED WITH VARIOUS SURFACE PREPARATIONS

### Test Pieces and Static Test Results

Several test pieces of 0.040-inch alclad 24S-T spot-welded after various surface preparations were furnished through the courtesy of Mr. C. W. Steward of Curtiss-Wright. Table 10 lists five groups of specimens. There were three groups of spot-welded test pieces prepared by different processes. For each of these groups, two lots of specimens (A and B) were prepared at different times with, inadvertently, slightly different welding conditions. For comparison of joint efficiencies, two groups (4 and 5) of riveted specimens were furnished.

Figure 8 shows photographs of three failed specimens. One illustrates the spot-weld pattern characteristic of groups 1, 2, and 3, having three rows of spots, with the distance between spots in each row 1/2 inch and the distance between rows 1/2 inch. The other two specimens shown in figure 8 illustrate the rivet patterns of groups 4 and 5.

Table 10 also shows static strength values and static joint efficiency values. It may be noted that the AC wire-brushed specimens had a static joint efficiency (95 percent) considerably higher than that (83 percent) of the strongest riveted joints.

#### Fatigue Test Results

Nine specimens of each group were furnished. At Mr. Steward's suggestion, three of those were run at each of three preselected loads.

Table 11 presents the results of the fatigue tests. The method of running the tests at three preselected loads brings out the features of scatter in test results. However, with so few load values, it is not feasible to draw load-life curves or to calculate fatigue joint efficiency values for various constant lifetimes. Nevertheless, figure 9 shows approximate load-life curves in the form of scatter bands which do not attempt to distinguish among the different spot-weld groups. From these curves and from a fatigue curve (reference 3, fig. 5) for alclad 24S-T sheet, limiting values of joint efficiencies may be estimated. Such values are given in table 12. Comparison of these values with values for other specimens tested (see sec. 5 of this report) indicates that these test pieces were strong in fatigue.

From table 11, it may be observed that, of the spot-welded specimens tested here, those made by DC welding wire-brushed surfaces appeared slightly the strongest in the fatigue tests. From table 11 and figure 9, it appears that those same spot-welded specimens were nearly as strong as the best riveted specimens.

#### Examination of Spot Welds

Figures 10, 11, and 12 show photographs of sectioned spot welds. Table 13 gives average values of spot-weld dimensions for samples from the various groups.

Careful examination of table 13 affords an interesting observation. For the AC wire-brushed pieces, specimen 7 had a smaller nugget area and a smaller total weld area than specimen 8 but an appreciably longer fatigue life. This may be connected with the larger corona area of specimen 7. A similar observation applies on comparing specimens 1 and 2. Generally the same observation applies on comparing DC welded specimens with each other. The apparently important contribution of corona bonding to fatigue strength does not appear to extend to the comparison of AC welds with DC welds.

### Conclusions

The following conclusions are suggested by the data described:

1. Spot-welded joints can be made to have as high static joint efficiencies and nearly as high fatigue joint efficiencies as riveted joints.
2. Of the three types of spot-welded specimens (AC - wire brush, DC - wire brush, and DC - chemically cleaned), the AC wire-brushed were strongest statically, but the DC wire-brushed strongest in fatigue.
3. There is a suggestion that, for a given type of welding (AC or DC), corona bonding contributes considerably to fatigue strength.

In view of the relatively small number of specimens, these conclusions must be regarded as tentative.

## IV. LAP-JOINT SPECIMENS WITH SPOT WELDS OF WIDELY

### VARYING SIZE AND STATIC STRENGTH

#### Test Pieces and Static Strength

Nine panels with spot welds of successively larger sizes were received, together with radiographs of all welds, from California Institute of Technology through the courtesy of Mr. R. C. McMaster.

Table 14 gives the welding conditions for each panel. Figure 13 shows photographs of spots illustrating the variation in

spot size. (See also figs. 15, 16, 17, and 18.) Table 15 gives the results of measurements of the various spot dimensions and also values of static shear strength from tests on single-spot coupons. The terms used to designate weld dimensions have been defined in a previous report. (See reference 2, p. 4.)

Examination of the welds and calculations from the data in table 15 showed that the corona area was nearly constant throughout the range of welds (0.0316 sq in. for Panel 1 to 0.0320 sq in. for Panel 9). On the other hand, the weld-nugget area increased from 0.0398 to 0.0804 square inch. The static shear strength increased approximately in direct proportion to the nugget area.

#### Fatigue Test Results

Strips 3 inches wide containing three spot welds each were sheared from the various panels and tested in fatigue. All tests were run at a load ratio  $R = 0.25$ .

Table 16 presents the results of the fatigue tests, and figure 14 shows load-life curves plotted from these data. To avoid confusion, only results for every odd-numbered panel have been plotted - results for other panels, in general, follow the same pattern.

Two observations are interesting. First, the spread in fatigue strengths is less than that in static-strength values. This seems particularly true for lower loads and longer lifetimes. Second, there is an increase in fatigue strength with increasing weld size and increasing static-strength values. Neither of these observations held for some previously reported tests on spot-welded lap joints (reference 2, p. 10). It seems that fatigue strengths may increase in the same order as static strengths, for welds varied in size only by varying the welding voltage.

#### Examination of Failed Specimens

Figures 15, 16, 17, and 18 show sections of spot welds from failed samples of the various panels.

It may be noticed that the smaller welds sheared at high loads but cracked from the elected protrusion at lighter loads. Larger welds "pulled buttons" (figs. 16d and 17a) at higher loads

and sometimes gave rise to failure in the sheet at lighter loads. Overheated and cracked welds (see fig. 18c) showed no signs of weakness in fatigue or of failure through the transverse crack.

## V. FATIGUE TESTS ON LAP JOINTS WITH VARIOUS SPOT-WELD PATTERNS

### Test Pieces and Static Test Results

Table 17 outlines a series of tests on the effect on fatigue strength of varying the spot-weld pattern in simple lap joints, and table 18 shows strength properties of the sheet material used. The purpose was to determine the effects of such variables as the number of rows of spots, the spacing between spots, staggering spots in adjacent rows, and post-rigging multi-rowed joints. The Boeing joint pattern has been included as representative of a joint that is successful in actual service conditions. Figures 19, 20, and 21 show photographs of various joint patterns.

Table 18 gives static test results on test pieces made from the various lots of sheet used for the spot-weld specimens.

Tables 19 and 20 give the welding conditions for the various jointed specimens. Figures 22, 23, and 24 show photographs of sectioned welds. In general, all welds were of good appearance. The one exception was for group 3 M2C, where welds appeared to be overheated.

Table 21 gives static strength values averaged for two representative specimens of each group. It may be observed that:

1. Increasing the number of rows decreases the strength per spot but increases total joint strength and joint efficiency. (Cf. results for 3 B1G-D, 3 K1C-D, and 3 M1C-D.)
2. A spot spacing of 1/2 inch appears to afford a strong joint. (Cf. 3 K1C-D and 3 K1C-F. Note also the high joint efficiencies in groups 3 M1C-F to 3 M3C-F.)
3. There does not appear to be any notable effect due to staggering spots in adjacent rows. (Cf. 3 K1C-D and 3 L1C-D.)

4. Post-aging (10 hr at 370° F) before welding appears to increase the static joint efficiency; while post-aging after welding may even decrease the static joint efficiency.

5. The pattern consisting of three rows of spots, with the spots 1/2 inch apart in each row and with the rows 1/2 inch apart, gave very high static strengths. Of the specimens used in these tests, this pattern produced the strongest joint in static strength (a joint stronger than the Boeing joints tested).

These results are in reasonable accord with test results reported in the literature (references 4 and 5).

#### Fatigue Test Results

To insure that the alclad 24S-T sheet used in making the spot-welded test pieces had normal fatigue strength properties, and to afford base curves for the evaluation of fatigue joint efficiencies, fatigue tests were run on samples of the particular lots of sheet materials used. The resulting data are given in tables 22, 23, and 24, and some of these data are shown as load-life curves in figures 25, 26, and 27. The values for the 0.040-inch sheet are nearly the same as those reported for other lots. (See reference 3, table 2.) Values for the 0.064-inch sheet are close to those for 0.040 inch. For both gauges, the effect of post-aging (10 hr at 370° F) on fatigue strengths was slight and was in the direction of reducing the fatigue strength (cf. reference 3, fig. 5). The 0.016-inch sheet tested appeared to have slightly higher fatigue strengths for lifetimes beyond  $10^6$  cycles at a load ratio of  $R = 0.25$  than either the 0.040- or the 0.064-inch sheet.

Tables 25 through 36 give the results of fatigue tests on the variously patterned joints. Most of the tests were run at the load ratio  $R = 0.25$  for which the alternating component of load is high, so that effects produced by dynamic loading might be expected to show up. In many cases, a few tests were run at a higher load ratio ( $R = 0.60$ ) in order to note any possible unexpected effect of varying the ratio. Figures 28 through 32 show the results plotted as load-life curves.

In particular, figure 28 shows fatigue test results for specimens of 0.040-inch sheet having one row of spots and for specimens having two rows of spots. It seems fair to conclude that:

1. Two rows of spots afford a joint more than 50 percent stronger than a single row.

2. It does not make much difference whether the spots in the two rows are staggered or in alignment.

3. Using a 1/2-inch spacing between spots in a row gives a stronger joint than a spacing of 3/4 inch, both in static tests and in fatigue tests at  $R = 0.25$ . However, the strength increase is somewhat dubious at lifetimes in excess of  $2 \times 10^6$  cycles.

Joint efficiency values will be discussed later.

Figure 29 shows load-life curves at  $R = 0.25$  for specimens having three rows of spot welds. It may be observed that:

1. Joints with the spots spaced 1/2 inch apart in each row were stronger in fatigue (as well as in static tests) than joints with spots spaced 3/4 inch apart. (Cf. 3 M1C-D and 3 M1C-F.)

2. Post-agging the sheet before joining increased the static strength and did not significantly affect the fatigue strength. (Cf. 3 M1C-F and 3 M3C-F.)

3. Post-agging the joints after welding decreased slightly both the static strength and the fatigue strength. (Cf. 3 M1C-F and 3 M2C-F.)

Figures 30 and 31 show load-life curves for specimens with the Boeing type joint. It is interesting to note the relatively large decrease in fatigue strength with decreasing load and lifetimes increasing to  $10^7$  cycles.

Figure 32 shows load-life curves for lap-joint specimens of 0.064-inch sheet. It will be noticed that the same general results hold for joints in 0.064-inch sheet as held for joints in 0.040-inch material.

Table 37 shows some values of joint efficiencies. Joint efficiency is here defined as the ratio of the strength per inch of joint to the strength-per-inch width of the sheet material at the same lifetime and at the same load ratio. Values for post-aged sheet were used for all jointed specimens post-aged either before or after welding.

Figure 33 shows smoothed-out curves of joint efficiency against lifetime plotted from the values in table 37. With one exception, the fatigue joint efficiencies preserve the same order as the static values. The fatigue values are always lower and decrease somewhat with decreasing load and increasing lifetime. The one exception is the curve for 3 NLE-D (three rows of spots in 0.064-in. sheet) which shows joint efficiencies decreasing rapidly with decreasing load and increasing lifetime. This trend can be observed, of course, in the steep load-life curves for these specimens. (See fig. 32.) No explanation will be attempted now. In comparing the Boeing joint (5 ULC-F) results with results for the other patterns, it must be kept in mind that these Boeing joints were made with roller welds. Previous tests (reference 3) have indicated that roller welds may be slightly weaker in fatigue than spot welds.

### Conclusions

Useful interpretation of the results noted above requires correlation with previously reported data and very careful consideration of the limitations necessary in drawing general conclusions from particular laboratory tests. It is believed desirable to omit premature conclusions from this progress report.

It may be observed that, in general, variations of fatigue strength with variations of spot-weld patterns have followed the order of variations in static strength.

## VI. FATIGUE TESTS ON LAP-JOINT SPECIMENS

### WITH VARIOUS RIVET PATTERNS

#### Test Pictures and Static Test Results

For purposes of comparison, tests were made on lap-joint specimens fastened by various patterns of flush rivets. Table

38 gives specifications for the test pieces and figures 34, 35, and 36 show photographs of the various types of joints. In choosing the rivet patterns, it was not the intention to duplicate exactly the spot-weld patterns but rather to use rivet spacings characteristic of good commercial practice.

Table 39 gives the results of static tests and shows static joint efficiency values (based on a static ultimate of 66,700 psi for the sheet as received and 69,000 psi for the post-aged sheet). The joint efficiency is here defined to be the strength per gross inch of the jointed specimen divided by the strength-per-inch width of a monobloc specimen of the same gage sheet.

It may be observed from the values listed in table 39 that:

1. For the single-row specimens (P1C-D and P1C-F), the 1/2-inch spacing gave a stronger joint than did the 3/4-inch spacing.
2. For the 3/4-inch spacing single row (P1C-D and P2C-D), the post-aged specimens gave a higher joint efficiency.
3. For specimens with two rows those (Q1C-D and T1C-D) with approximately 3/4-inch spacing between rows were stronger than those with closer spaced rows. Of these two, Q1C-D, which had its rivets in line, appeared stronger than T1C-D in which the rivets were staggered.

#### Fatigue Test Results

Tables 40 through 45 show the results of fatigue tests on the various specimens. Figures 37, 38, 39, and 40 show various load-life curves plotted from these data.

Figure 37 shows curves at three load ratios for group P1C-D (a single row of rivets spaced 3/4 in. apart). The dotted line shows, for  $R = 0.25$ , the curve for the same type of specimens post-aged (P2C-D). Apparently, although post-aging increased the static joint strength, it slightly decreased the fatigue strengths except at very high loads and very short lifetimes.

Figure 38 shows curves (solid lines) for specimens (P1C-F) with rivets spaced 1/2 inch apart. The specimens with the closer spaced rivets appear stronger both statically and in fatigue.

The strength difference is most marked at very low loads and long lifetimes. For example, at a lifetime of  $3 \times 10^8$  cycles at a load ratio  $R = 0.25$ , the  $\frac{3}{4}$ -inch spacing gives only about 60 percent the strength of the  $\frac{1}{2}$ -inch spacing.

Figure 39 shows curves at  $R = 0.25$  for specimens with rivets  $\frac{3}{4}$  inch apart in each row. The increase in strength on adding a second row  $\frac{3}{4}$  inch away is evident on comparing the two curves. The effect of staggering the spots for the two-row pattern is insignificant. (Both observations apply generally to fatigue curves at  $R = 0.60$ .)

Figure 40 shows the load-life curves for three groups of specimens, all of which had a pattern consisting of two rows of staggered rivets spaced  $\frac{3}{4}$  inch apart in each row. The spacing between rows varied from  $\frac{3}{16}$  to  $\frac{11}{16}$  inch. Apparently, joints with the largest spacing between rows were strongest, being above that for the specimens (3 B1C-D) with a single row of spot welds and generally near the curve for specimens (3 L1C-D) with two rows of spots. Again the curve for specimens (3 L1C-D) with two rows of rivets lies very near that for specimens (3 M1C-F) with three rows of spot welds.

With the possible exception of the curve for a single row of rivets, the order of the joint efficiencies in fatigue is much the same as that for static values (fig. 4). Thus, while the results indicate a generally lower joint efficiency in fatigue than in static tests, they imply that riveted joints are better than spot-welded ones in fatigue only as they are also better statically (fig. 42). It also appears possible that spot-welded joints can be made that are as strong in fatigue as riveted joints at the possible expense of having an extra row of spot welds.

(1) These comparison values have been taken from previously reported work. In general the welding conditions were similar to those given in Table 1.

(2) Static values were obtained at Battelle on six spot specimens exactly like those tested in fatigue. Values reported by the welders for single spot coupons vary slightly from those given above but show exactly the same order for different gages.

AC - Alternating current

DC - Direct current

WB - Wire brush cleaned

CC - Chemically cleaned

\* Area assumed bonded. The extent of bonding was estimated from the appearance of welds after the sheets were torn apart.

TABLE 14. WELDING CONDITIONS FOR PANELS FROM CALIFORNIA INSTITUTE OF TECHNOLOGY

Material:	0.040" to 0.040" Alclad 268-T	
Machine:	Taylor-Winfield Hi-wave, condenser discharge welder, 440 line volts.	
Electrode pressure:	1100 lbs.	(constant)
Capacitance:	960 mfd.	(constant)
Voltage:	-----	(variable)
Throat:	8 inches	(constant)
Arm:	9 1/2 inches	(constant)
Radius top electrode	4 inches	(constant)
Radius bottom electrode	4 inches	(constant)
Material cleaned in Oakite #63 and Oakite #64		
Panel No.	Voltage	
1	1350	
2	1500	
3	1600	
4	1700	
5	1800	
6	1925	
7	2025	
8	2125	
9	2250	

TABLE 12. APPROXIMATE JOINT EFFICIENCIES FOR SPECIMENS WITH VARYING SURFACE PREPARATIONS

Specimen Type	Joint Eff. in Per Cent at Various Lifetimes				
	10 <sup>4</sup> Cycles	5 x 10 <sup>4</sup> Cycles	10 <sup>5</sup> Cycles	5 x 10 <sup>5</sup> Cycles	10 <sup>6</sup> Cycles
Spot welded	54-63	38-47	31-42	30-38	- - 39
Riveted	58-64	42-47	40-44	36-41	36-41

Above are approximate limiting values from the scatter bands shown in Figure 3. Calculations use gross area in both cases and sheet data from Reference 3 page 302.

TABLE 16. PROPERTIES OF SPOT WELDS FROM CALIFORNIA INSTITUTE OF TECHNOLOGY SPECIMENS

Panel Number	Avg. Weld Nugget Diameter		Avg. Corona Diameter (1)		Average Penetration, Inches	Max. Offset from Center Line, Inches	Max. Indentation on One Side, Inches	Average (2) Static Shear Strength, Pounds/Spot	Remarks
	Radiographs, Inches	Micrographs, Inches	Radiographs, Inches	Micrographs, Inches					
1	0.131 $\pm$ 0.010	0.102 $\pm$ 0.010	0.214 $\pm$ 0.010	0.225 $\pm$ 0.001	0.020 $\pm$ 0.003	0	0.004	230 $\pm$ 30

(1) P2C-D specimens were post-aged after riveting.

(2) S denotes rivets in adjacent rows staggered, L rivets in line.

#### Riveting Procedure

1. All material 0.040" Alclad 24S-T.
2. Rivets AN426AD-5, 100° countersunk, 5/32 D.  
Rivet material Al7S-T specification An-FF-R551.
3. Both sheets drilled with hand motor using #21 (0.159") drill.  
Holes burred with countersunk type burring tool.
4. Surface skin dimpled 100° on one shot rivet gun (Chicago Pneumatic).
5. Sub-dimpled other skin 110° on same equipment.
6. Riveting performed with a Chicago Pneumatic Squeezer.

TABLE 39. STATIC TEST RESULTS FOR RIVETED LAP JOINT SPECIMENS

Specimen Designation	Static Ultimate Values (1)			Static Joint Eff. (%) (2)
	Total Lbs.	Lbs./Rivet	Lbs./Inch
